## Introduction

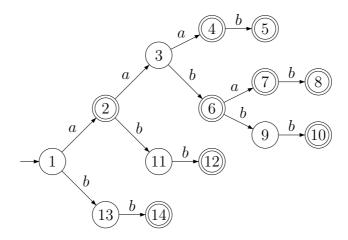

Given any text x, the task of detecting the positions of x where a set of patterns can be found is usually known as pattern matching or string matching. This problem is of algorithmic interest and plays an important role in many fields, such as Molecular Biology or Genetics, because it allows fast processing of biologic sequences.

A first *naive* approximation to the problem is to carry out an individual search of each pattern in the text. This leads to a complexity of  $\mathcal{O}(n \cdot |p| \cdot |x|)$ , where n is the number of patterns to locate, |p| is the length of the longest pattern and |x| is the length of the text. In this practice we will study how a non-deterministic approach can help to solve the problem.

To do so, for any given set M of words over some alphabet  $\Sigma$ , we consider the *prefix tree acceptor* for M (PTA(M)), which is defined as the DFA that accepts exactly the language M. For instance, taking into account the set:

$$M = \{a, bb, aaa, aab, abb, aaab, aaba, aabab, aabbb\}$$

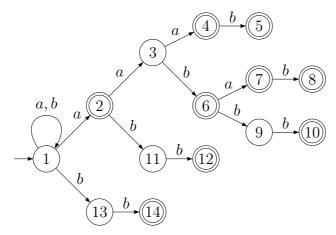

the PTA(M) would be:

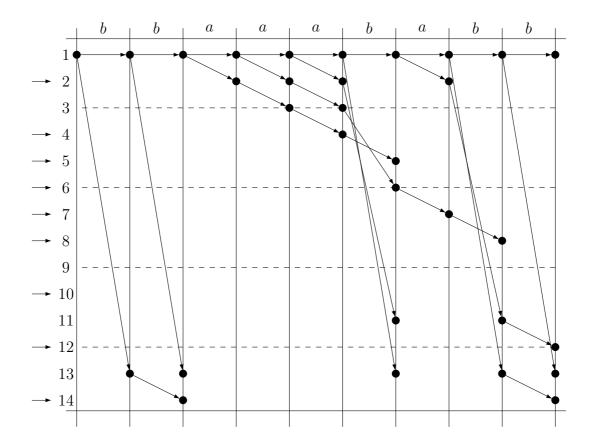

More formally, the PTA(M) is defined as the automaton  $A = (Q, \Sigma, \delta, q_0, F)$  where:

- $Q = \{ x \in \Sigma : x \in Pref(M) \}$
- $q_0 = \lambda$
- $\blacksquare F = M$
- $\delta(x,a) = xa$  if  $xa \in Q$ , and undefined otherwise

This automaton can be easily modified to obtain a NFA to accept the language  $\Sigma^*M$ . To carry out such modification, note that it is enough to add a loop on the initial state with every symbol in the alphabet. Taking into account the previous automaton, the result of the operation is shown below.

This automaton is useful to locate each position of a text x where a string in a set M can be found. Note that, to do so, it is enough to carry out a, slightly modified, non-deterministic parsing of x. Whenever a final state is reached it is possible to say that a pattern has been found. For instance, let us consider the text x = bbaaababb. The analysis is represented in the trellis below:

The diagram allows to detect, for instance, that once the second symbol has been processed, state 14 is reached. This state is final, thus, a pattern in M has been found (pattern

bb). In the same way: the analysis of bba and bbaa lead to reach the state 2, which means that pattern a has been found; and, the analysis of bbaaa lead to reach the states 2 and 4, or in other words, the patterns a and aaa have been found.

## **Exercises**

### Exercise 1

Design a Mathematica module to return the set of prefixes of an input set M

#### Exercise 2

Implement a Mathematica module to return the set of suffixes of an input set M

### Exercise 3

Implement a Mathematica module that, on input of a set of strings M, returns the prefix tree acceptor of M

### Exercise 4

Design a Mathematica module that, on input of a set of strings M, return a NFA that accepts the language  $\Sigma^*M$ 

### Exercise 5

Implement a Mathematica module that, on input of a NFA A and a string x, returns whether  $x \in L(A)$  or not

#### Exercise 6

Design a Mathematica module that, on input of a set of patterns M and a text x, returns the set of positions of x where a pattern in M can be found
